7.1	Potential Valid Inequality	4

1 Valid Inequality 1

$$\sum_{v \in V} x_{vi} \geq \left\lceil \frac{|V|}{K} \right\rceil \quad (1)$$

Explanation This constraint requires the first block of the partition to contain at least $\lceil |V|/K \rceil$ vertices. Since the vertex set V is divided into exactly K nonempty blocks, the average block size is $|V|/K$. By the pigeonhole principle, at least one block must contain at least $\lceil |V|/K \rceil$ vertices. Assigning this requirement to block 1 is valid because of the symmetry-breaking constraints that enforce a nonincreasing block size order:

$$\sum_{v \in V} x_{v,i} \geq \sum_{v \in V} x_{v,i+1}, \quad \forall i \in \{1, \dots, K-1\}.$$

Thus, block 1 can be designated as the largest block without loss of generality. This inequality preserves feasibility, strengthens the LP relaxation by ruling out artificially balanced fractional solutions, and reduces solver symmetry by eliminating weakly balanced partitions.

2 Valid Inequality 2

$$\sum_{v \in V} x_{vi} \leq \left\lfloor \frac{|V| - K + i}{i} \right\rfloor \quad \forall i \in \Pi \quad (2)$$

Explanation Let $s_j := \sum_{v \in V} x_{v,j}$ denote the size of block j . The model enforces (i) nonemptiness $s_j \geq 1$ for all j , (ii) a nonincreasing order $s_1 \geq s_2 \geq \dots \geq s_K$, and (iii) $\sum_{j=1}^K s_j = |V|$. Fix i . Since the last $K-i$ blocks must contain at least $K-i$ vertices in total, the first i blocks can use at most $|V| - (K-i)$ vertices:

$$\sum_{j=1}^i s_j \leq |V| - K + i.$$

Under the ordering, the configuration that maximizes s_i given $\sum_{j=1}^i s_j$ is to set $s_1 = \dots = s_i$, hence

$$i \cdot s_i \leq |V| - K + i \implies s_i \leq \frac{|V| - K + i}{i}.$$

Integrality of s_i yields

$$s_i \leq \left\lfloor \frac{|V| - K + i}{i} \right\rfloor,$$

which matches the proposed inequality.

Tightness and Special Cases. The bound is tight, e.g., when $s_1 = \dots = s_i = \left\lfloor \frac{|V| - K + i}{i} \right\rfloor$ and $s_{i+1} = \dots = s_K = 1$ (whenever the sum equals $|V|$). For $i = 1$ it reduces to $s_1 \leq \lfloor |V| - K + 1 \rfloor$, and for $i = K$ it gives $s_K \leq \lfloor |V|/K \rfloor$, consistent with the interpretation that the smallest block cannot exceed the average size.

3 Valid Inequality 3

$$d_{vi} \geq \sum_{u \in CN(v)} x_{u,i} - |CN(v)| + 1 \quad \forall v \in V, \forall i \in \Pi \quad (3)$$

Explanation This inequality links the domination variable $d_{v,i}$ with the assignment of v 's neighbors to block i . Its logic is as follows:

- If **all neighbors of v** are assigned to block i , then

$$\sum_{u \in CN(v)} x_{u,i} = |CN(v)|,$$

and the right-hand side equals 1. Hence, the constraint enforces $d_{v,i} \geq 1$, which forces $d_{v,i} = 1$. That is, vertex v must dominate block i .

- If at least one neighbor of v is not in block i , then

$$\sum_{u \in CN(v)} x_{u,i} \leq |CN(v)| - 1,$$

and the right-hand side is nonpositive. Since $d_{v,i} \geq 0$, the inequality becomes redundant and places no restriction.

Thus, the inequality ensures that **whenever block i consists entirely of neighbors of v** , the model must recognize this by setting $d_{v,i} = 1$. In other words, it eliminates the possibility that a vertex is “silently” dominating a block without the variable $d_{v,i}$ reflecting it.

4 Valid Inequality 4

$$d_{vi} \leq \sum_{u \in CN(v)} x_{ui} \quad \forall v \in V, \forall i \in \Pi \quad (4)$$

Explanation This inequality ensures that vertex v can only be declared as a dominator of block i if at least one of its neighbors is assigned to block i . In other words, domination is not allowed in a vacuum: the variable $d_{v,i}$ cannot take the value 1 unless there is some vertex in block i that v is actually adjacent to.

- If no neighbor of v lies in block i , then the right-hand side equals 0, and the constraint enforces $d_{v,i} = 0$.
- If one or more neighbors of v belong to block i , then the inequality permits $d_{v,i}$ to be 1, but does not require it.

Thus, this constraint acts as a **logical upper bound**: it rules out false positives where a vertex is labeled as a dominator of a block that contains none of its neighbors.

5 Valid Inequality 5

$$\sum_{v \in S} d_{vi} \leq 1 \quad \forall S \in \mathcal{I}, \forall i \in \Pi \quad (5)$$

Explanation This inequality leverages structural information from the squared graph G^2 , in which two vertices are adjacent if their distance in the original graph G is at most two. By construction, a maximal independent set in G^2 consists of vertices that are pairwise at distance at least three in G . Such vertices cannot jointly dominate the same block, because domination requires adjacency relationships that are incompatible with this distance condition.

Therefore, the inequality enforces that **at most one vertex from any maximal independent set of G^2 can dominate a given block**.

- If two or more vertices from the same independent set S were both chosen as dominators of the same block, then the block would need to simultaneously be contained within the neighborhoods of these vertices. But since their neighborhoods are too far apart in G , this is impossible.
- The inequality thus cuts off such infeasible configurations at the linear relaxation level, strengthening the formulation without excluding any valid dominator partition.

This family of inequalities integrates higher-order graph structure into the model and systematically restricts domination assignments that are combinatorially impossible.

6 Valid Inequality 6

$$\sum_{u \in CN(v)} x_{ui} \leq |CN(v)| - 1 + d_{vi} - \sum_{\substack{y \in S \\ y \neq v}} d_{yi} \quad \forall v \in V, \forall S \in \mathcal{I} \text{ with } v \in S, \forall i \in \Pi \quad (6)$$

Explanation This inequality couples the “all-neighbors-in-the-block” trigger for v with the exclusivity requirement induced by the maximal independent set MIS in G^2 . Specifically:

- If **all neighbors of v** lie in block i , then $\sum_{u \in CN(v)} x_{ui} = |CN(v)|$, and the inequality becomes

$$|CN(v)| \leq |CN(v)| - 1 + d_{v,i} - \sum_{y \in \text{MIS} \setminus \{v\}} d_{y,i},$$

which simplifies to

$$1 \leq d_{v,i} - \sum_{y \in \text{MIS} \setminus \{v\}} d_{y,i}.$$

Hence, $d_{v,i}$ must be 1 and **all other** $d_{y,i}$ with $y \in \text{MIS} \setminus \{v\}$ must be 0. In words: when block i is entirely within $N(v)$, vertex v is forced to be the **unique** dominator from MIS for that block.

- If **not all neighbors of v** are in block i , then $\sum_{u \in CN(v)} x_{u,i} \leq |CN(v)| - 1$, so the left-hand side is at most $|CN(v)| - 1$, and the inequality becomes nonbinding: it does not force any particular value of $d_{v,i}$ (nor of the other $d_{y,i}$).

Thus, the constraint acts as a **cover-type coupling inequality**: it activates only in the event that block i is fully contained in $N(v)$, and in that case it both (i) forces v to dominate block i and (ii) enforces **exclusivity** among the dominators drawn from the same maximal independent set of G^2 .

7 Valid Inequality 7 (fractional seed = 1265)

$$\sum_{v \in V \setminus \{u, w\}} x_{vi} \geq d_{u1} \quad \text{s.t. } u \text{ is pendant, } (u, w) \in E, i \in \{\Pi \setminus \{1\}\} \quad (7)$$

Explanation This inequality exploits the special structure of pendant vertices to tighten the formulation. A pendant vertex u has exactly one neighbor w . The logic is as follows:

- If $d_{u,1} = 1$, then vertex u is chosen to dominate block 1. Since u can only dominate vertices in its neighborhood, and its only neighbor is w , it follows that block 1 must contain vertex w . Therefore, no other vertex except w can be in block 1, as that would violate the domination condition. The inequality then enforces that all other vertices (i.e., all vertices in $V \setminus \{u, w\}$) must be assigned to blocks other than block 1.
- If $d_{u,1} = 0$, then the inequality becomes non-restrictive, as the right-hand side is zero. In this case, there is no requirement on the assignment of other vertices.

7.1 Potential Valid Inequality

$$d_{u1} = 0 \iff \frac{n}{k} > \deg(u) + 1 \quad (8)$$

Explanation This potential inequality leverages the relationship between the average block size and the degree of a vertex u . The logic is as follows:

- If the average block size $\frac{n}{k}$ exceeds $\deg(u) + 1$, then it is impossible for vertex u to dominate block 1. This is because u can only dominate a block of size at most $\deg(u) + 1$ (itself plus its neighbors). Since the first block is the largest block due to the ordering constraints, it must be at least of size $\lceil \frac{n}{k} \rceil$.
